Tehnica frotiului sanguin

Frotiul de sange periferic este un preparat microscopic care reprezinta o picatura de sange ce se intinde intr-o pelicula foarte fina pe suprafata unei lame de sticla si care, dupa ce a fost fixat si colorat, se poate examina.

Sangele se recolteaza prin inteparea pulpei degetului inelar la adulti si a pielii calcaiului sau a tegumentului lobului urechii la nou-nascut si copilul mic.

Picatura de sange astfel obtinuta este depusa pe o lama de sticla curata si cu ajutorul altei lame este intinsa in strat subtire si uniform.

Urmeaza tehnica colorarii frotiului sanguin, in practica medicala cel mai des se utilizeaza tehnica de colorare panoptica May-Grunwald-Giemsa.

Rezultatele coloratiei:

Citoplasma: - la ***granulocite*** apare colorata in ***roz-caramiziu***;

- la ***agranulocite*** in ***diferite nuante de albastru***.

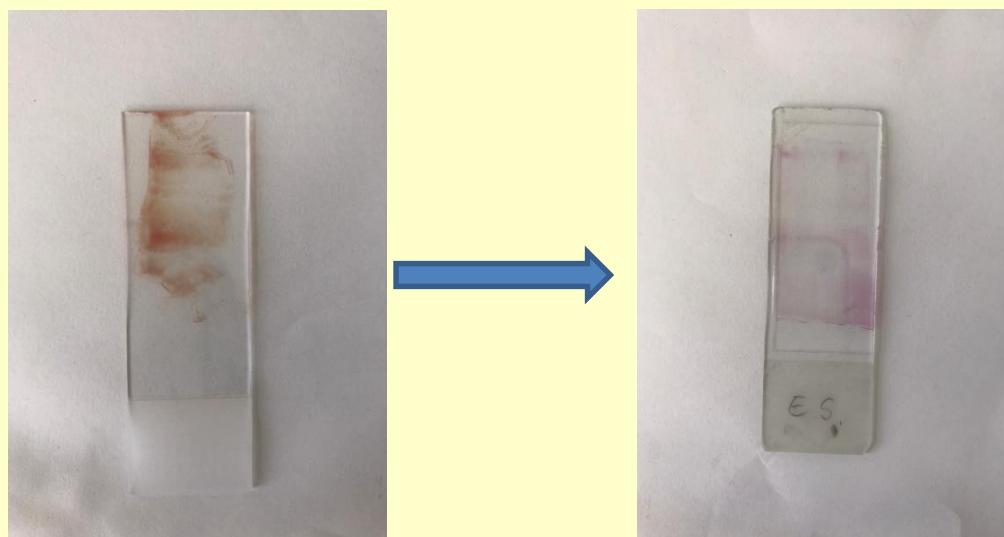

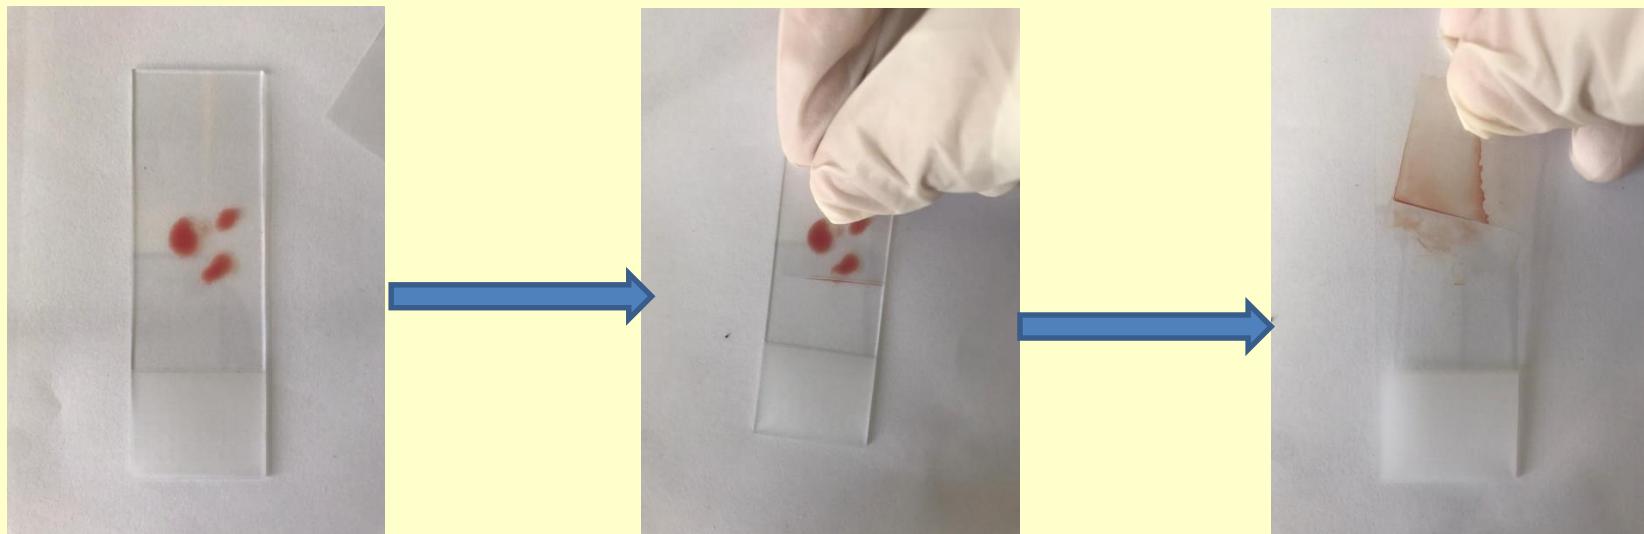

Granulatiile: - ***neutrofilele*** apar colorate ***violet***;

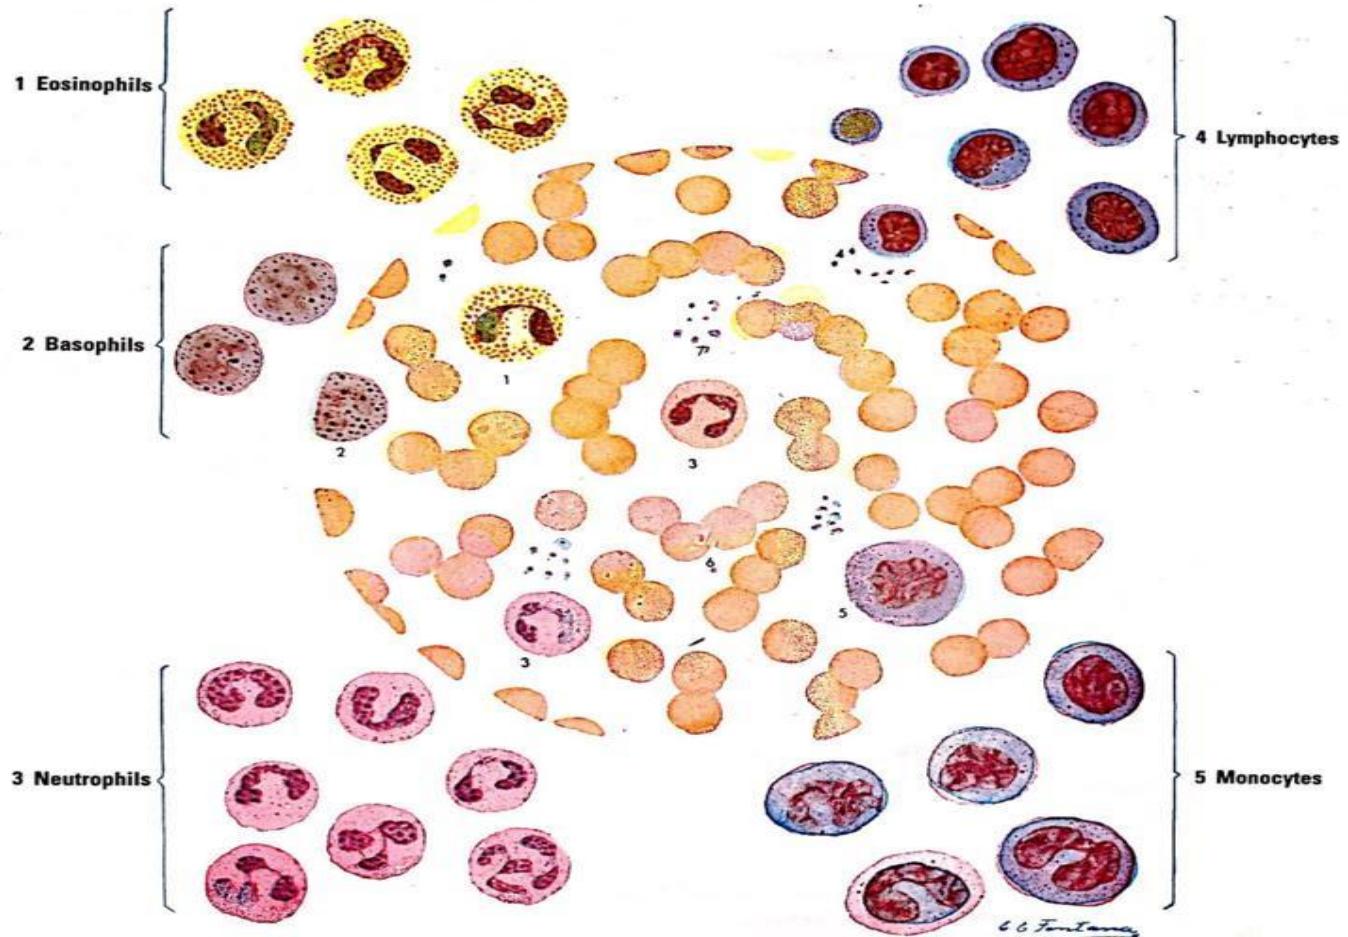

- ***acidofilele*** apar colorate in ***rosu***;

- ***bazofilele*** sunt ***albastre***;

- ***azurofilele*** apar ***rosu-violet***.

Stain: May-Grünwald-Giemsa. 1100×.

Schema frotiu de sange periferic. Dupa di Fiore's

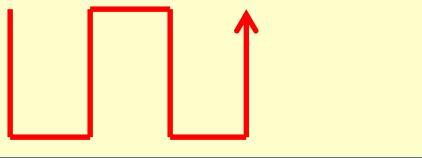

Formula leucocitara

Formula leucocitara este un examen cantitativ al frotiului de sange. Reprezinta raportarea procentuala a fiecarui tip de leucocite.

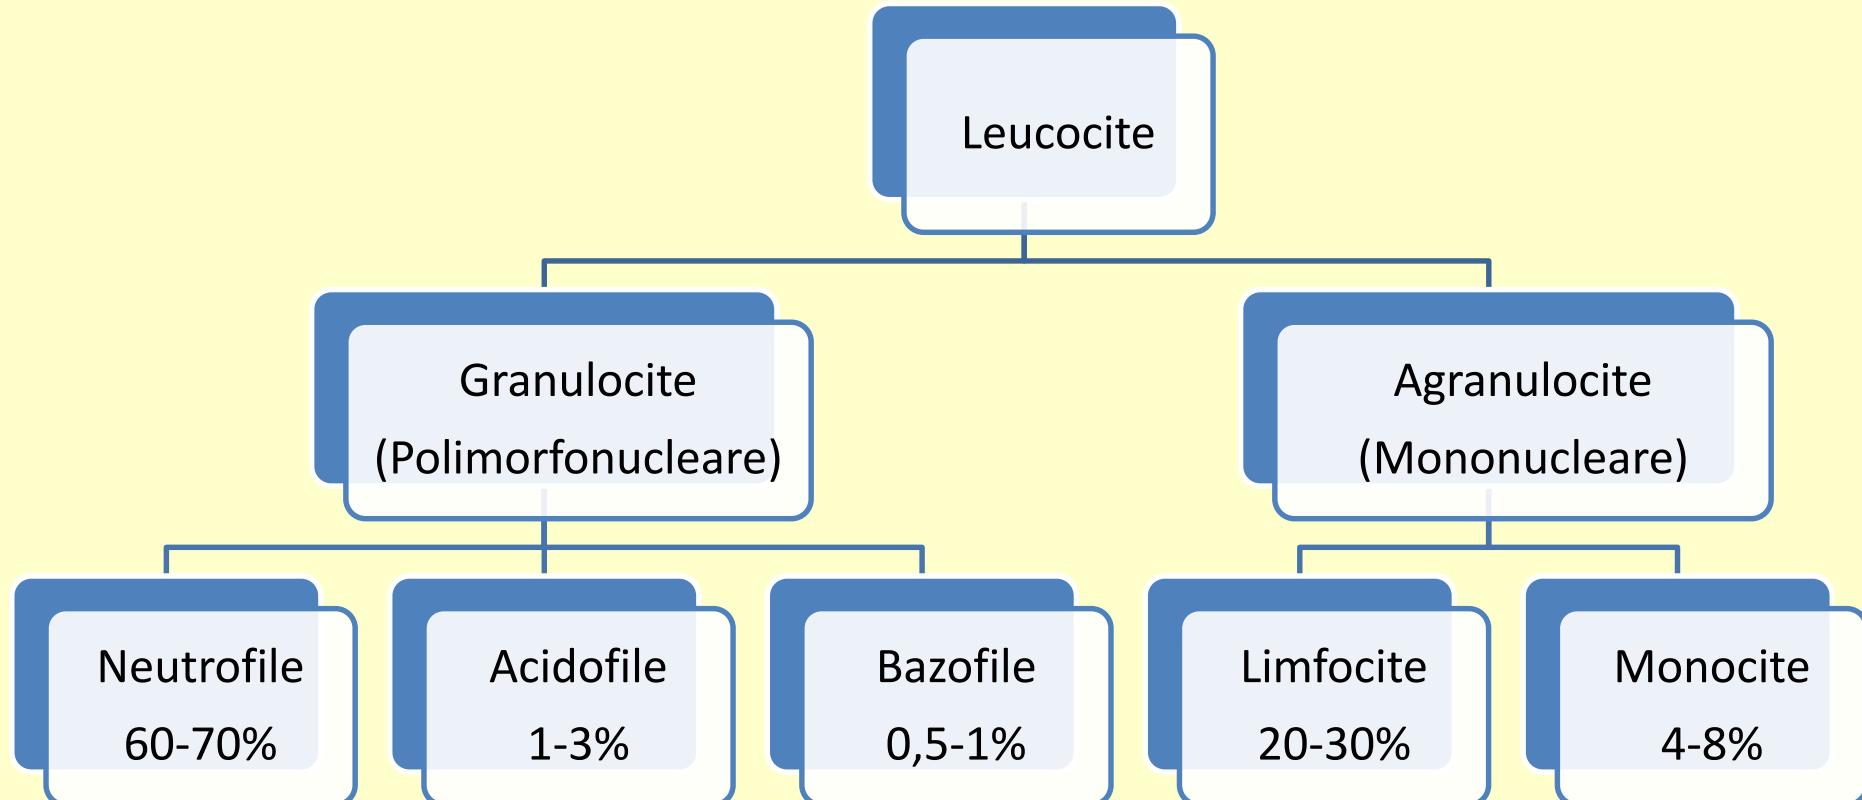

Examinarea frotiului de sange se face la microscop cu obiectivul cu imersie. Datorita tendintei de fuga spre periferie a leucocitelor ce duce la o densitate mai mare a lor la periferia frotiului comparativ cu zona centrala, este indicata citirea acestora atat in zona centrala cat si la periferie.

Formula de calcul :

$$\frac{\text{nr total leucocite dintr-un grup}}{\text{nr total leucocite numarate}} * 100$$

polimorfonucleare			mononucleare	
neutrofile	acidofile	bazofile	limfocite	monocite
				

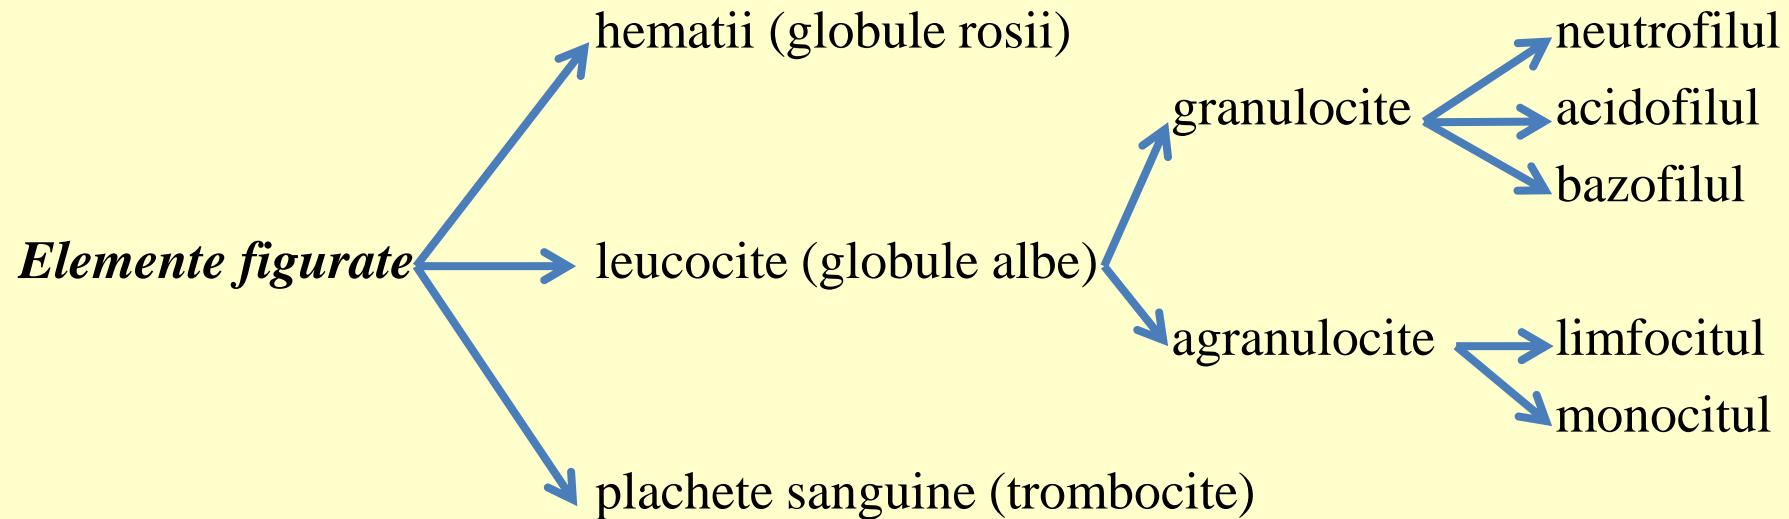

Formula leucocitara

Sangele-caracteristici

Sangele este o varietate de tesut conjunctiv cu substanta fundamentala lichida, de origine mezenchimatoasa, adaptat functiei de transport.

Este alcătuit din: **elemente figurate si plasma sanguina**.

Plasma sanguina este **partea lichida** a sangelui care mentine in suspensie elementele celulare sanguine. Din punct de vedere biochimic este formata din **apa** (90%), **substante organice** (9%) si **substante anorganice** (1%).

Hematiile

Numar → 4,5-5,5 milioane/mm³ la barbati

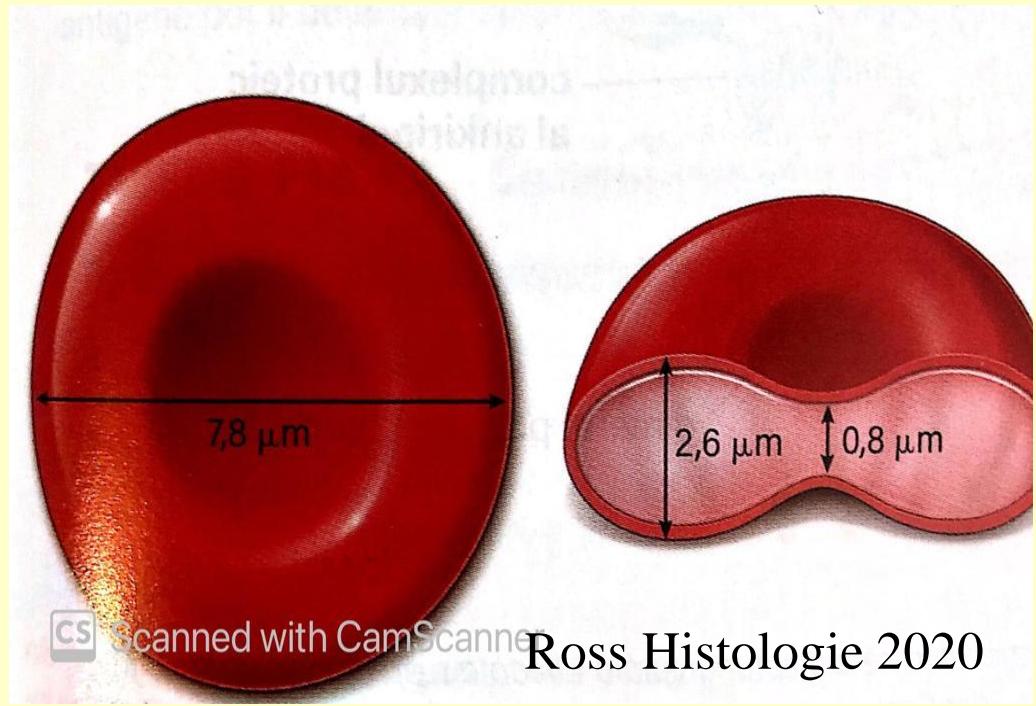

→ 4-5 milioane/mm³ la femei

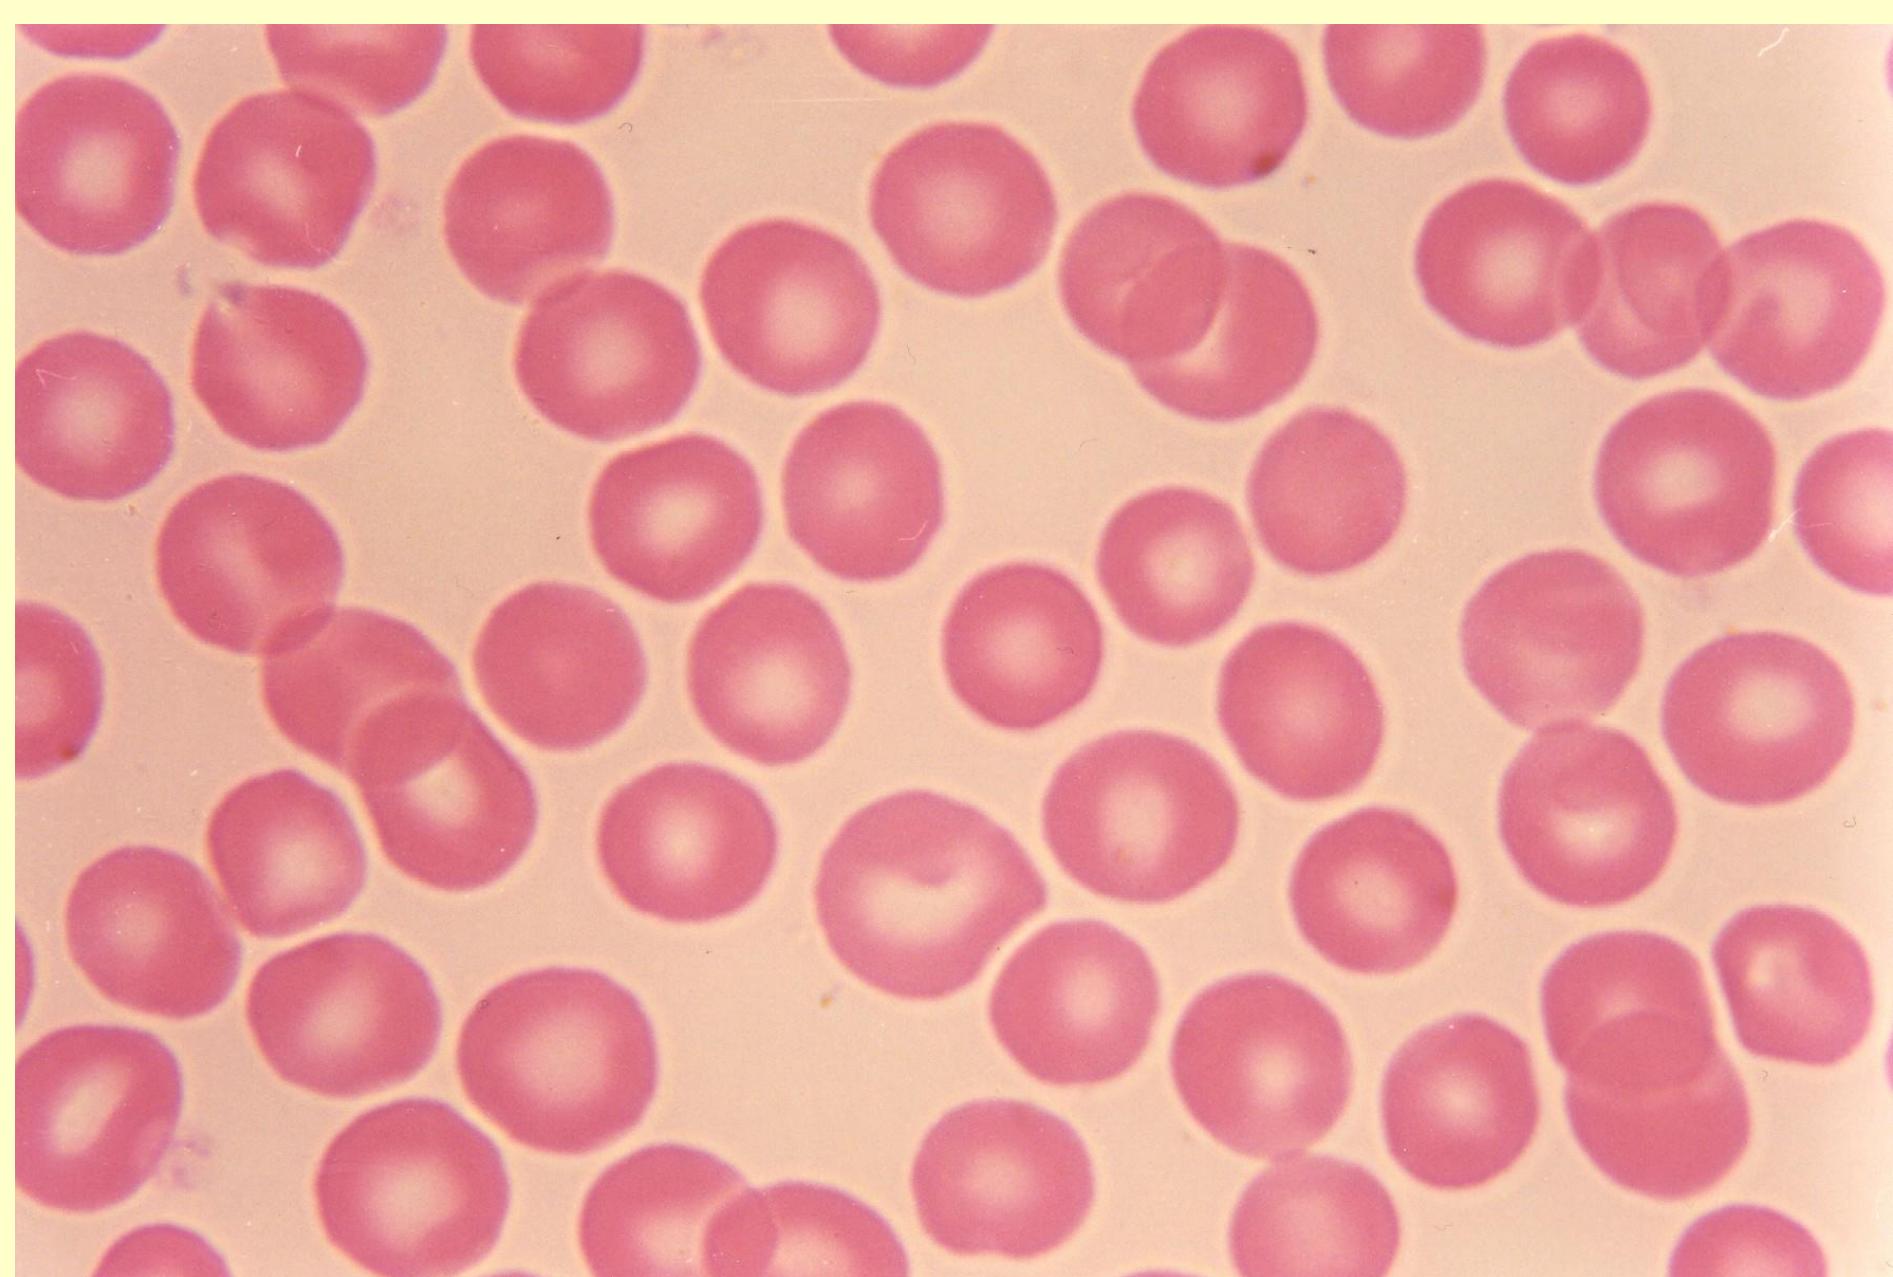

Forma → disc biconcav din profil

→ rotunda din fata

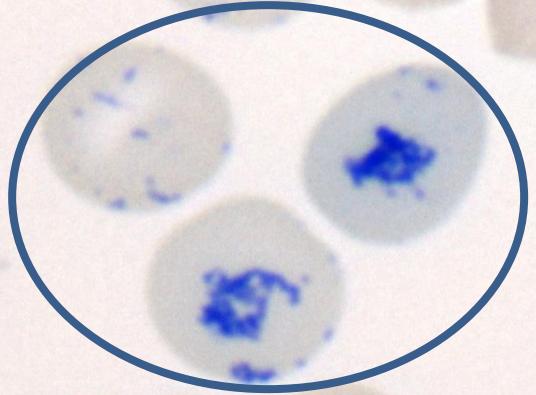

Diametru → 7-7,5 μm

Culoare → rosie

Frotiu de sange periferic. Hematii. Coloratie May-Grunwald-Giemsă

Reticulocite . Coloratie Violet cresyl

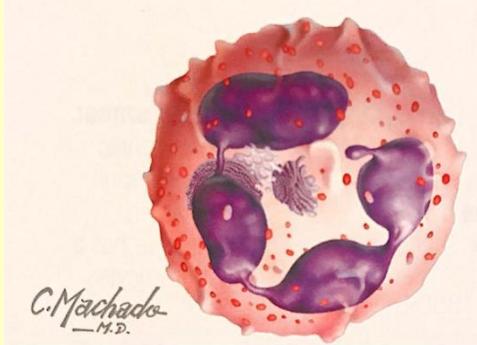

Polimorfonuclearul neutrofil

Forma → sferică

Diametrul → 10-12 µm

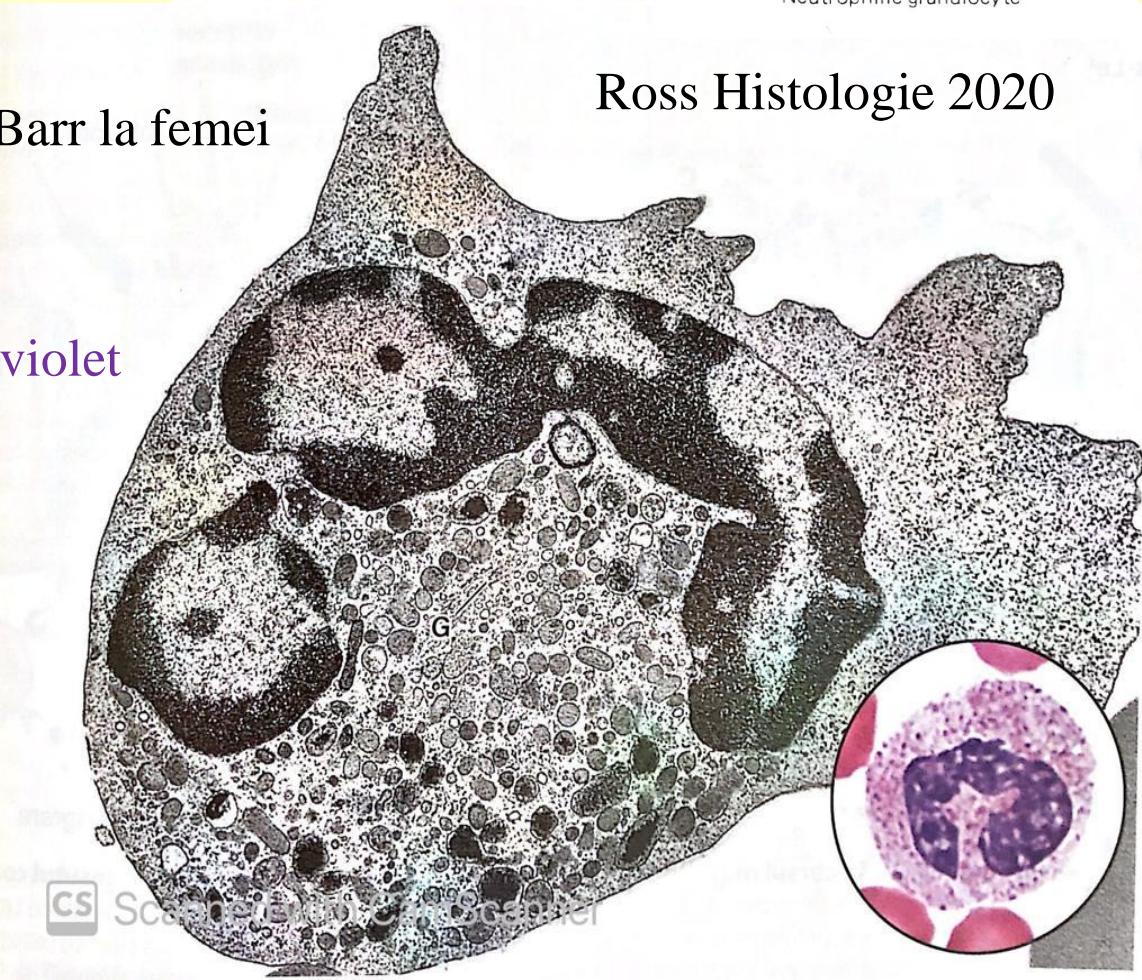

Nucleul ↛ 3-4 lobi
corpusculul sexual Barr la femei

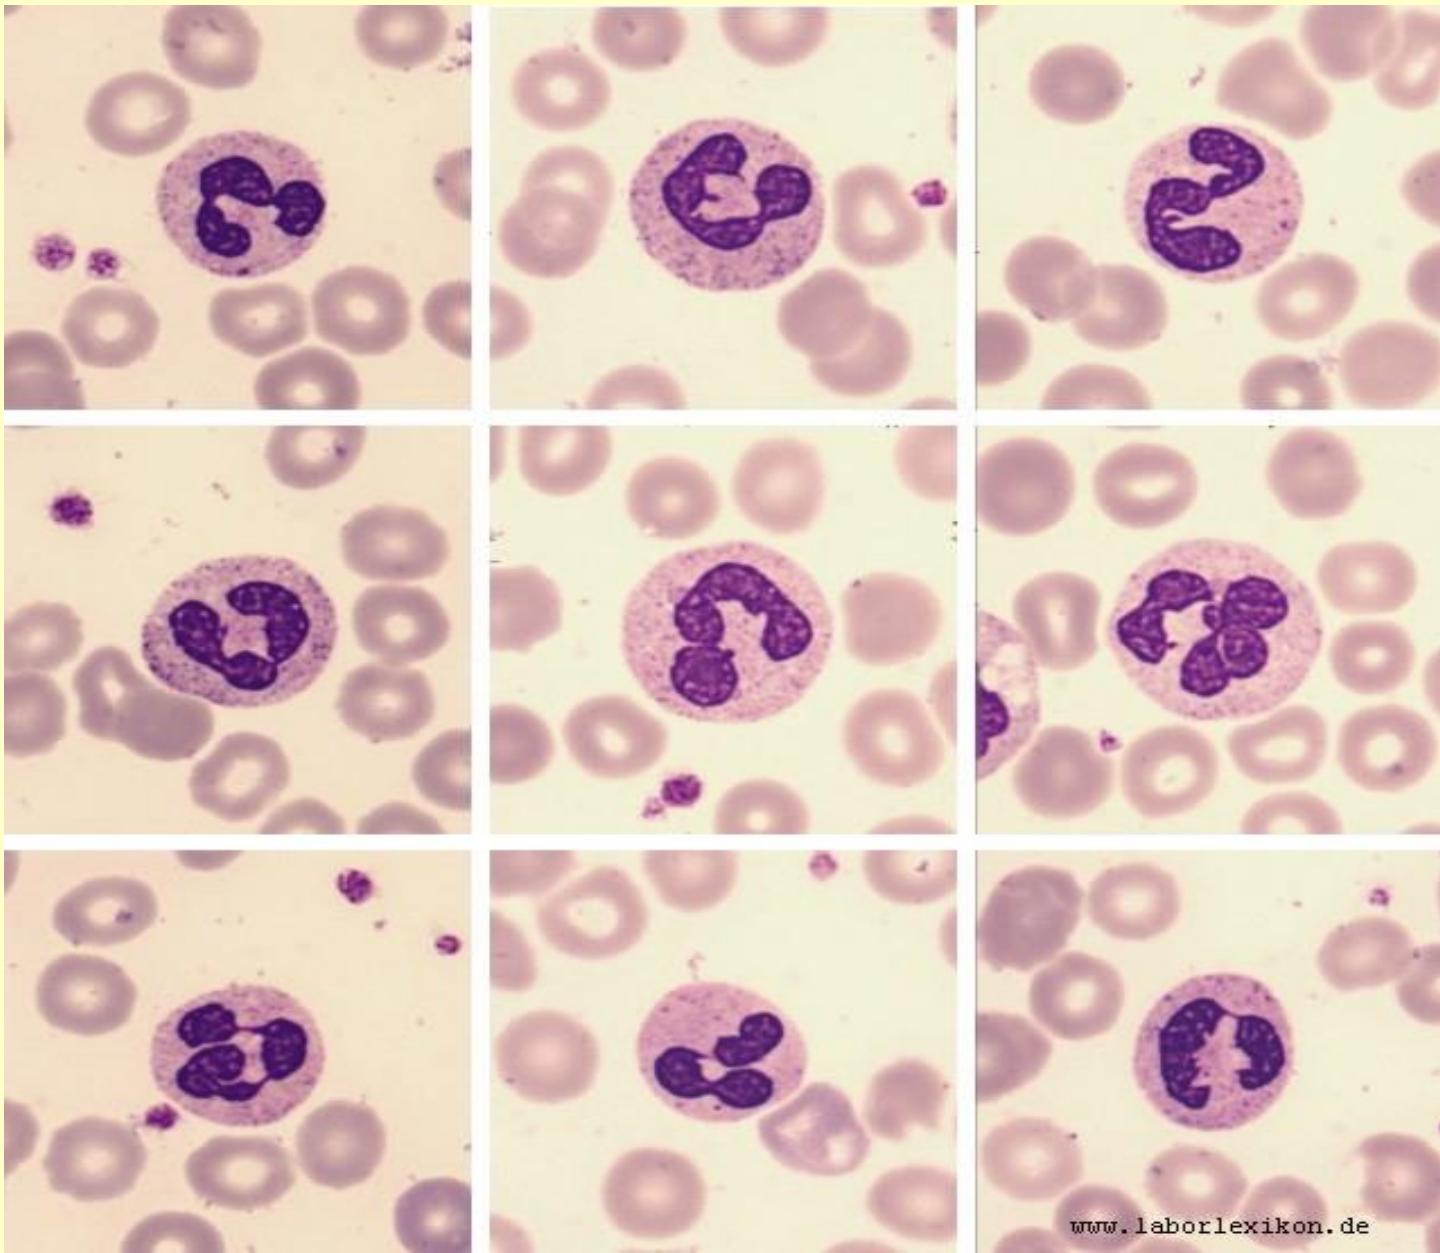

Citoplasma ↛ acidofila
granule epsilon → violet

Neutrophilic granulocyte

Frotiu de sange periferic. Hematii si Monocit. Coloratie May-Grunwald-Giemsa

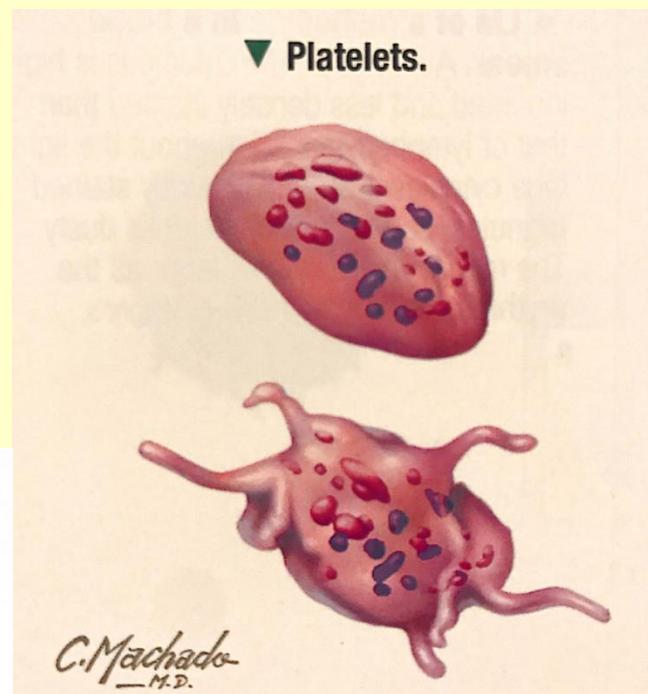

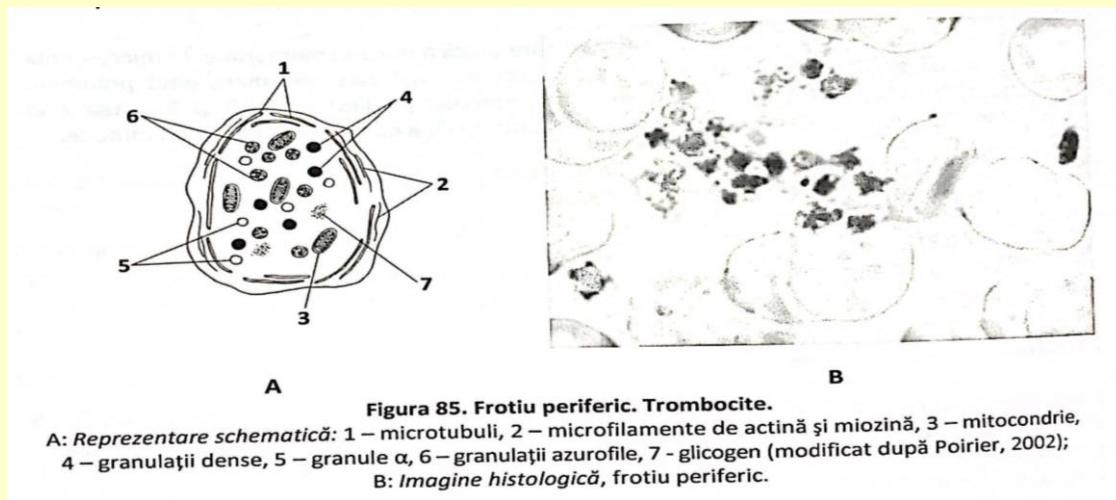

Trombocitele

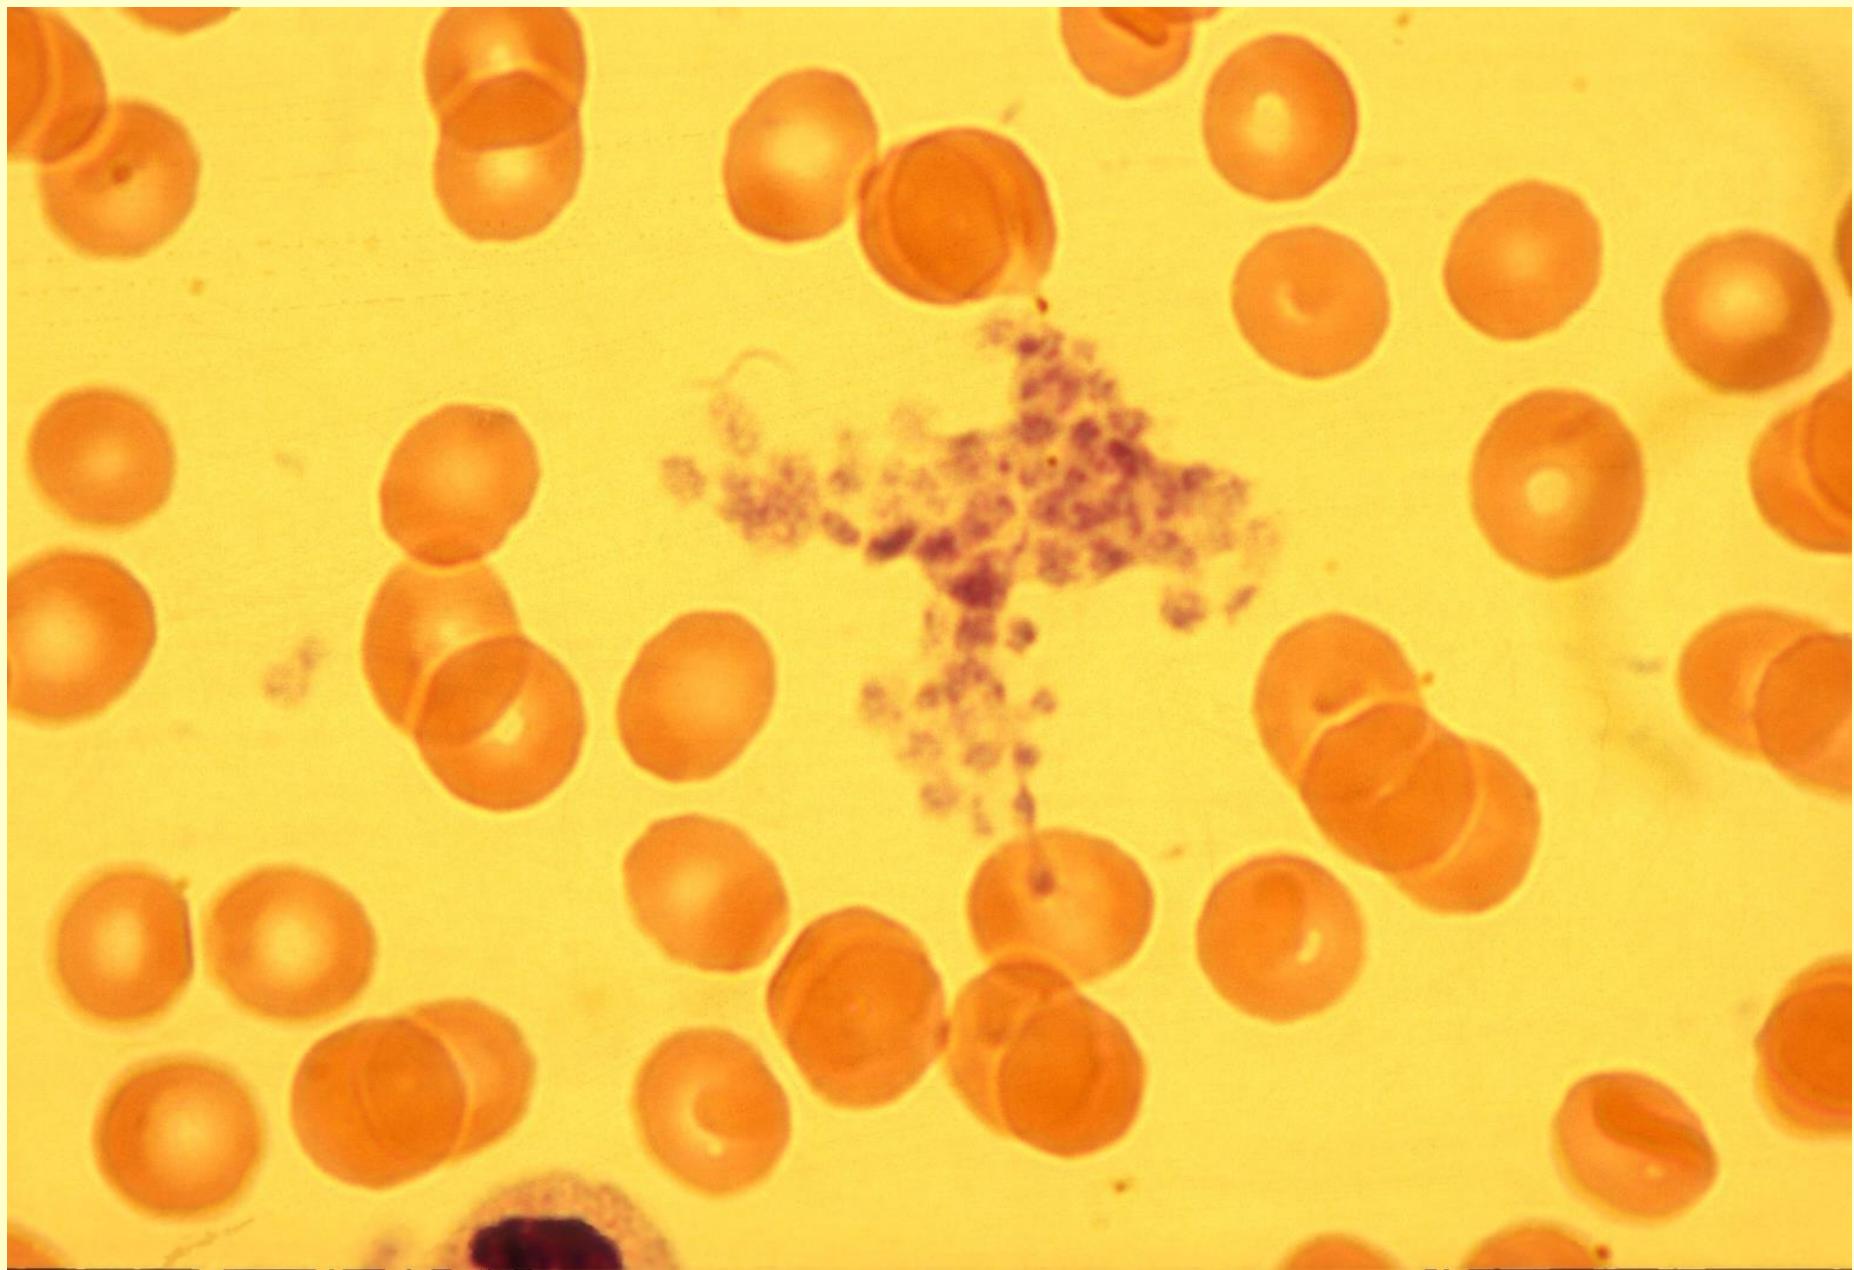

Trombocitele sunt denumite și *plachete sanguine*, sunt cele mai mici elemente figurate ale sangelui și reprezinta fragmente din citoplasma megacariocitului trombocitogen din hemomedula. *Nu au nucleu* și pe frotiul de sange periferic apar izolate sau grupate.

Forma

- elipsoidala în vasele de sânge
- pe frotiul fixat au forme diferite

Diametrul → 3-5 μm

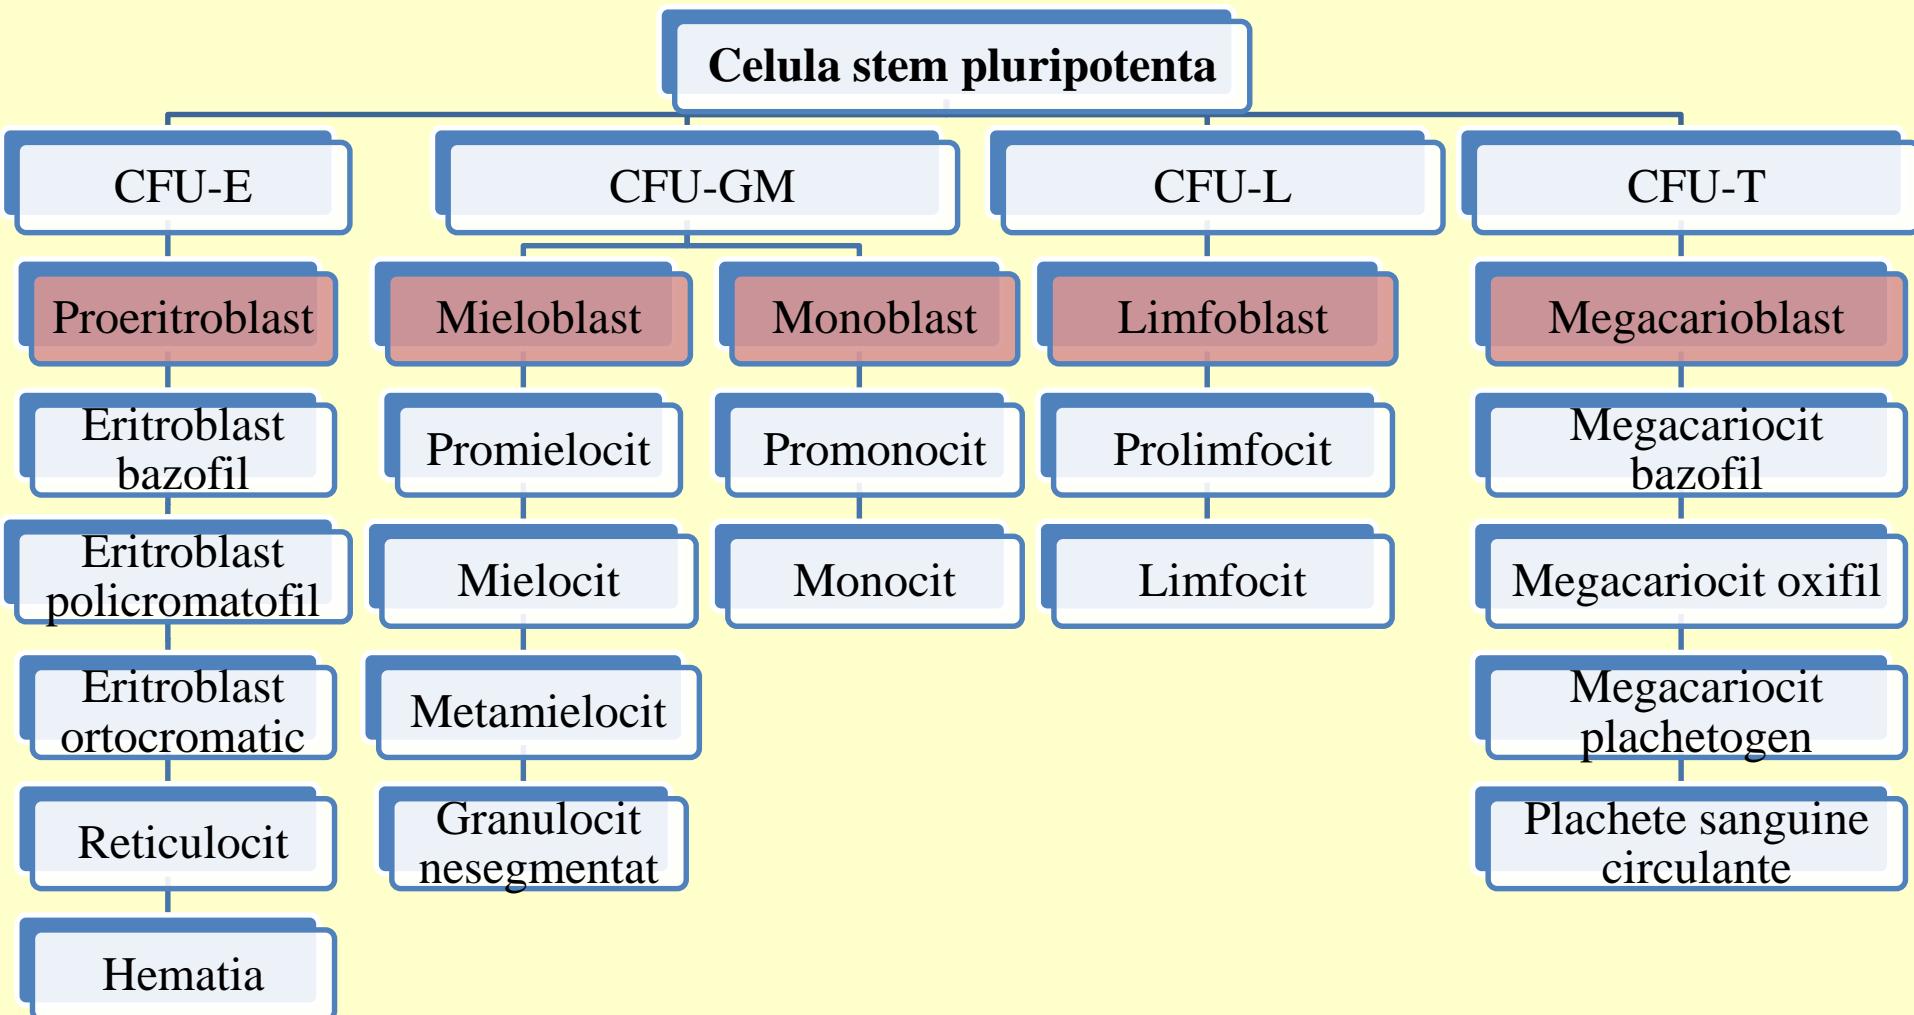

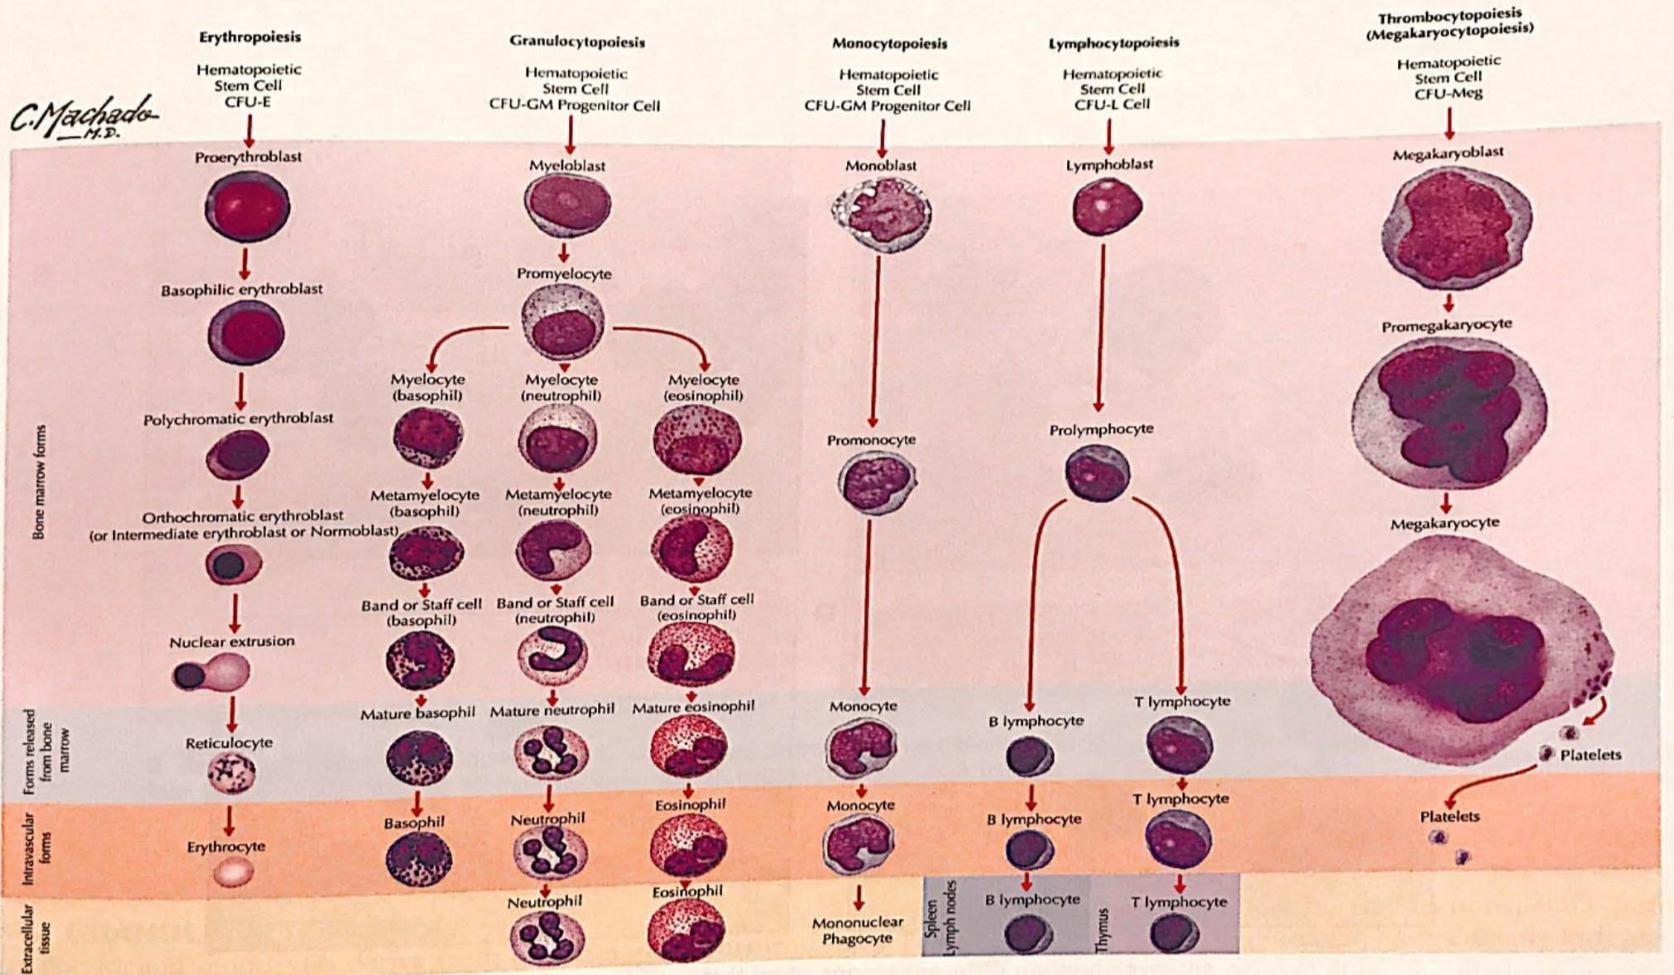

Frotiu de sange periferic. Hematii si Trombocite. Coloratie May-Grunwald-Giemsa

Hematopoieza

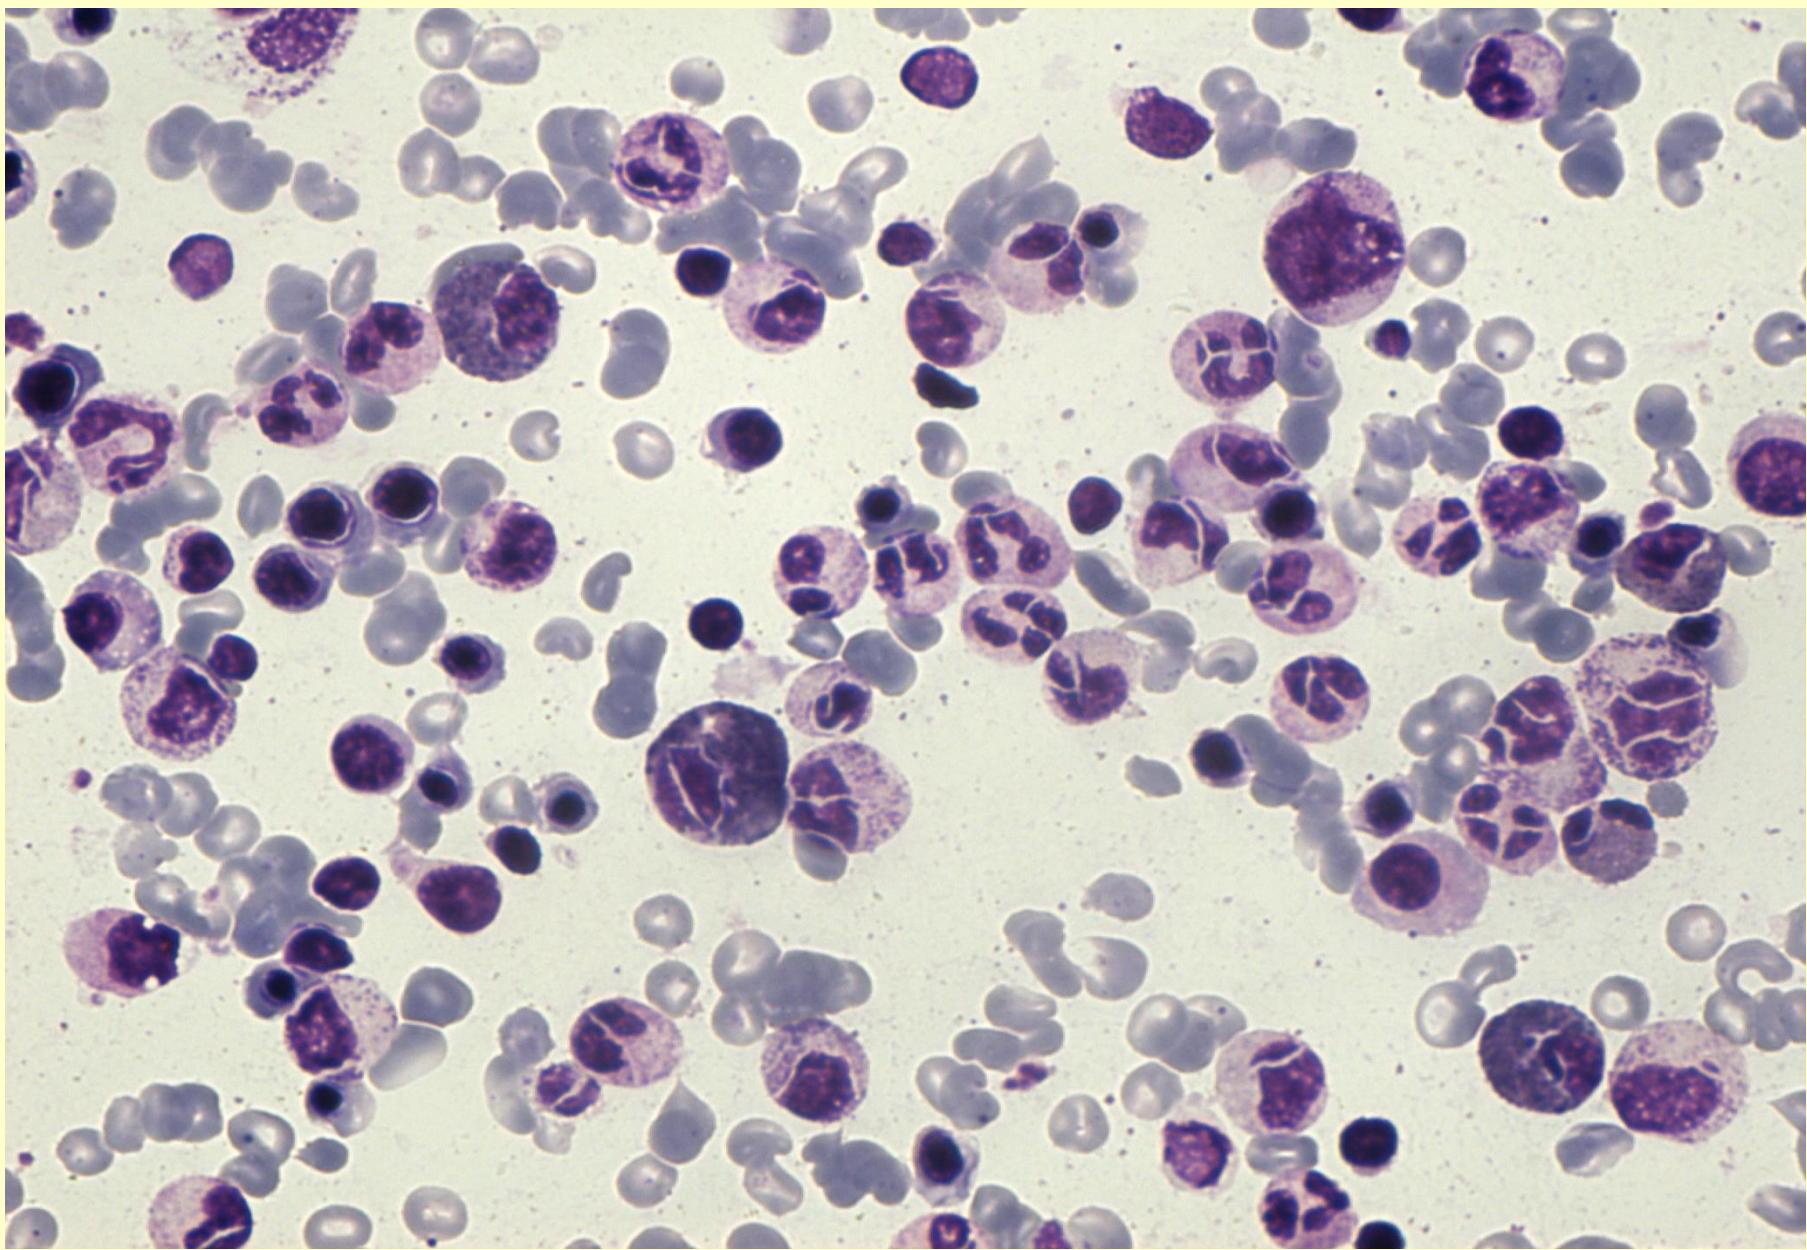

Hematopoieza reprezinta procesul de formare a elementelor figurate ale sangelui. Acest proces se desfasoara in tesutul hematopoietic (tesutul mieloid si tesutul limfoid).

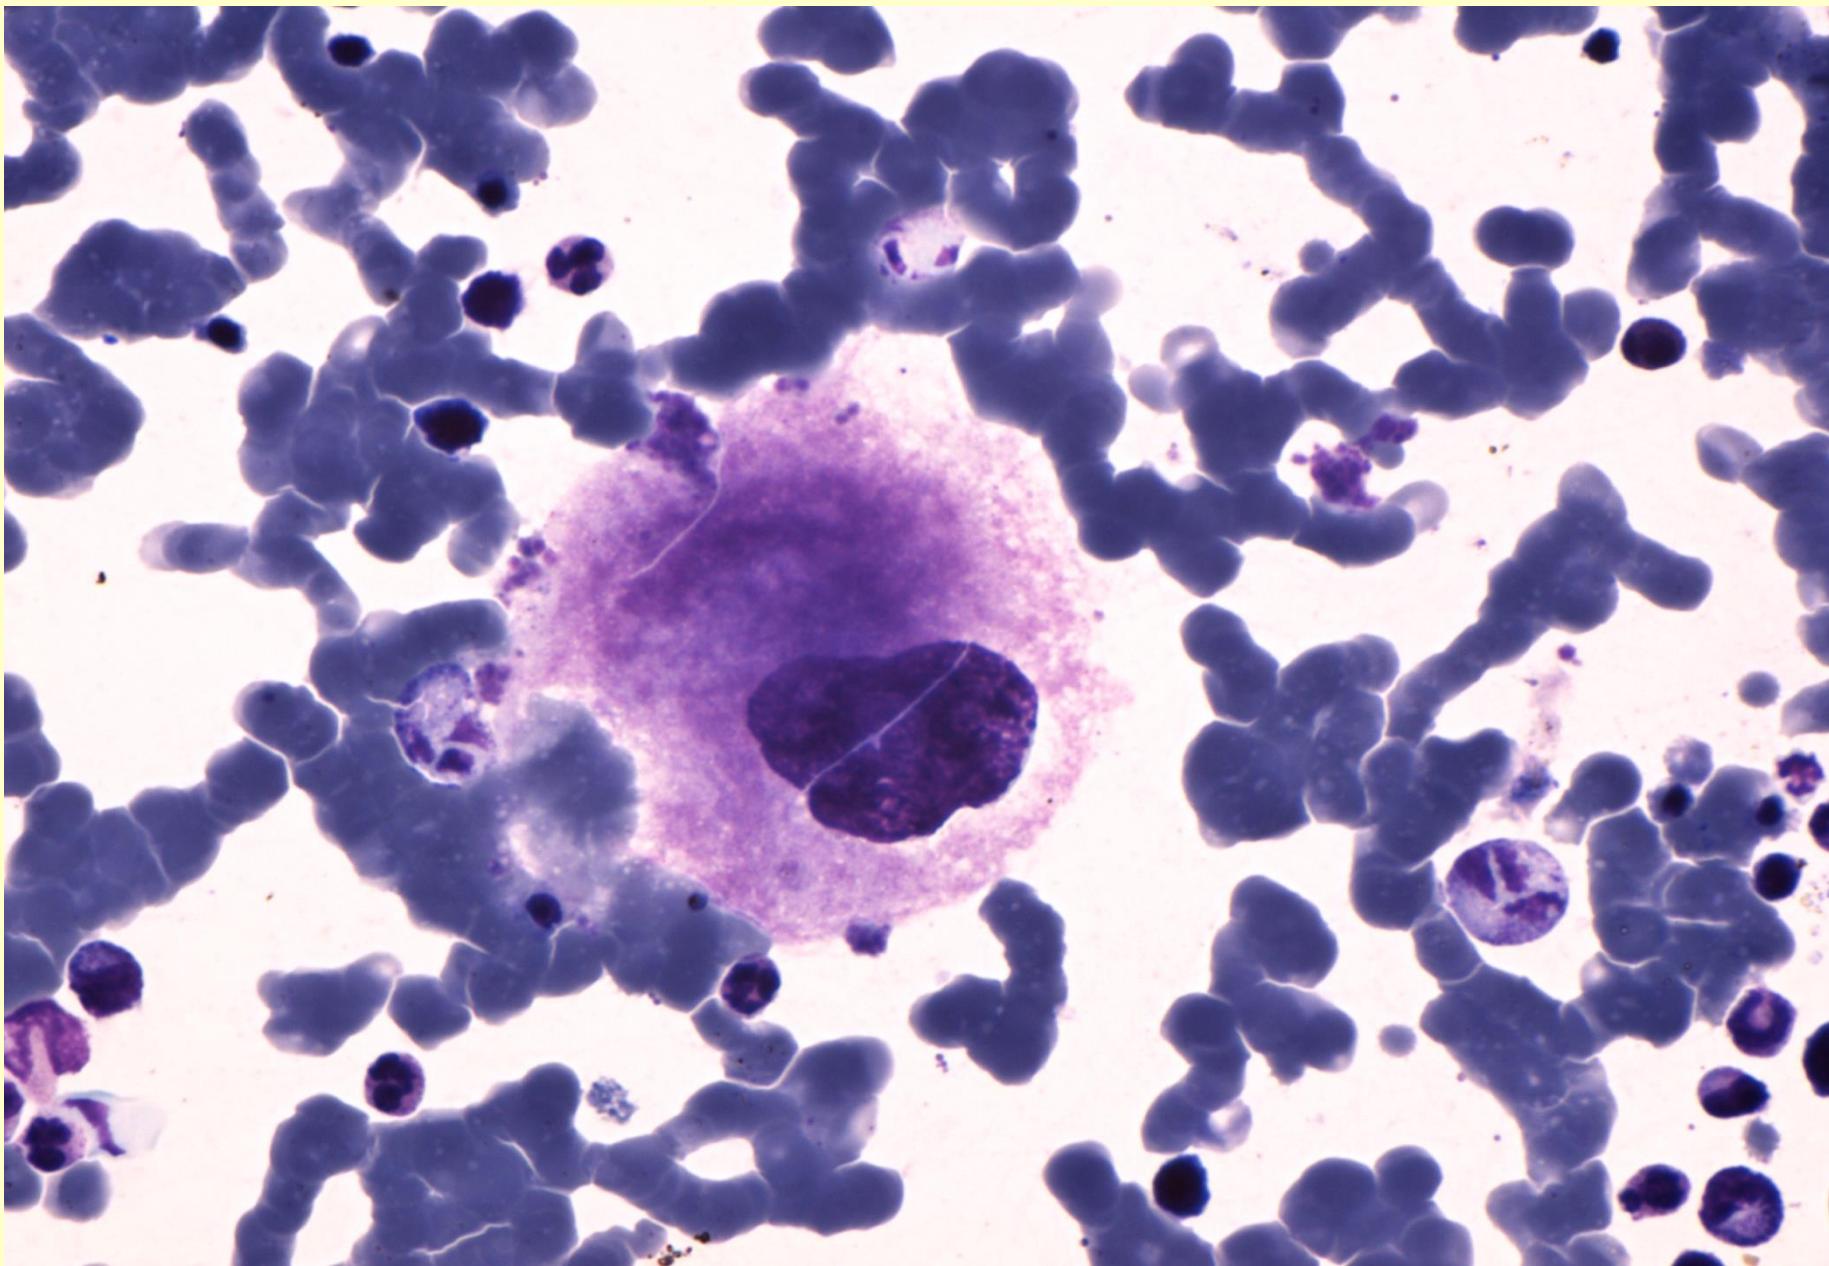

▲ **Schematic showing stages of hematopoiesis.** Although not all cells are included in each sequence, main cell types seen in bone marrow smears are shown in erythropoiesis (**Left**), granulocytogenesis (**Center, Left**), monocytogenesis (**Center, Right**), lymphocytogenesis (**Center, Right**), and megakaryocytopoiesis (**Right**). The various CFU cells that arise from the hematopoietic stem cell (not shown) closely resemble lymphocytes. Except for megakaryocytes, cells in erythroid and myeloid series as a rule get smaller during differentiation. Also, nuclear size declines, nuclear density increases, and special features related to cell lineage—such as hemoglobin production and nuclear extrusion in erythropoiesis, and specific granules (eosinophilic, basophilic, or neutrophilic) in granulocytogenesis—appear. Various growth factors and cytokines mediate cell proliferation rate and survival and maturation of progenitor cells. Some of these are colony-stimulating factors, erythropoietin, thrombopoietin, interleukins (IL-1, IL-3, IL-6, IL-11), and stem cell factors.
